READINESS

The Honorable Daniel K. Inouye
Chairman
Subcommittee on Defense
Committee on Appropriations
United States Senate
Washington, DC 20510

DEC 17 2012

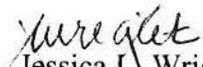

Dear Mr. Chairman:

The enclosed report responds to section 723 of the National Defense Authorization Act for Fiscal Year 2012 (Public Law 112-81) that requires the Secretary of Defense submit to the congressional defense committees an assessment of neuroimaging research for the purpose of improving the identification and diagnosis of post-traumatic stress disorder (PTSD). Activities related to PTSD fall under my purview, and I am pleased to provide the enclosed report.

The report reveals that current research findings do not support the specific use of neuroimaging techniques to identify or diagnose PTSD in individual patients. However, while the use of neuroimaging for these purposes is still experimental, research findings have significantly improved our understanding of the brain abnormalities in groups of patients with PTSD. Future brain imaging research could help identify individuals at risk for developing PTSD, categorize different types of PTSD, serve as a diagnostic tool for PTSD, and assist in making informed choices about individualized treatment with medications or psychotherapy.

A similar letter has been sent to the chairmen and ranking members of the other congressional defense committees. Thank you for your interest in the health and well-being of our Service members, veterans, and their families.

Sincerely,

Jessica L. Wright
Acting Principal Deputy

EXECUTIVE SUMMARY

Current research findings do not support the specific use of neuroimaging techniques to identify or diagnose Posttraumatic Stress Disorder (PTSD) in an individual patient. However, neuroimaging research has advanced our overall understanding of PTSD with the potential to impact diagnosis in the future.

Neuroimaging research findings have significantly improved our understanding of the brain abnormalities in groups of patients with PTSD. Future brain imaging research has the potential to help identify those at risk for developing PTSD, categorize different types of PTSD, serve as a diagnostic tool for PTSD, and assist in making informed choices about individualized treatment with medications or psychotherapy (talk therapy).

The DoD currently funds 23 neuroimaging research projects in the areas of PTSD and traumatic brain injury (TBI), headed by principal investigators from the Department of Veterans Affairs (VA), academia, and Draper Laboratory (see Appendices for discussion and list of studies). The VA and the National Institute of Mental Health (NIMH) currently fund 8 and 14 neuroimaging studies in PTSD, respectively.

INTRODUCTION

The National Defense Authorization Act for Fiscal Year 2012, Section 723, required that the Secretary of Defense submit a report assessing the benefits of neuroimaging research in an effort to identify and improve the diagnosis of PTSD. This report also considers the potential benefits of research using techniques for wounded, ill, and injured Service members with PTSD and explores collaborative interagency and extramural research in this area.

Despite the increasing prevalence of PTSD in Service members from the Operation IRAQI FREEDOM, Operation ENDURING FREEDOM, and Operation NEW DAWN conflicts, there is no objective lab-based test that can accurately diagnose PTSD. Currently, a diagnosis of PTSD is made by a trained clinician, based on a comprehensive clinical interview and assessment of an individual's self-reported symptoms. A diagnosis of PTSD can be made if an individual meets 8 out of 19 symptom criteria for PTSD (according to the Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition, Text Revision), and experiences either significant distress or impaired functioning for more than one month. Neuroimaging techniques can identify changes in the brain associated with mood and anxiety disorders, and have been investigated as a potential diagnostic tool for PTSD.

In response to the Congressional requirement for this report, the DoD conducted an extensive review of the PTSD literature using PubMed.gov (National Center for Biotechnology Information, U.S. National Library of Medicine). Conclusions in this report are based on the literature reviewed (Appendix E) and input from subject matter experts in the DoD and VA.

DISCUSSION

I: Benefits of Neuroimaging Research in an Effort to Identify and Improve the Diagnosis of PTSD

Seven neuroimaging techniques were critically evaluated for their potential use in diagnosing PTSD. Peer-reviewed publications in PTSD and structural magnetic resonance imaging (MRI), functional MRI (fMRI), diffusion tensor imaging (DTI), magnetic resonance spectroscopy (MRS), positron emission tomography (PET), single-photon emission computed tomography (SPECT), and magnetoencephalography (MEG) were examined (See Appendix C for bibliography). Each of these techniques provides a unique set of data that can be used to assess potential differences between groups of patients with and without PTSD.

Neuroimaging technologies detect average differences in brain structure (the anatomy or how the brain is built) and function (what each part of the brain does) between groups of patients with and without PTSD. However, the brain imaging abnormalities that are reported in PTSD are often inconsistent, partly due to variations in study design and other methodological limitations. The most consistent brain changes in PTSD are related to the smaller size of the hippocampus (brain structure related to memory), increased function of the amygdala (brain structure related to processing of fear), and the smaller size and decreased function of the medial prefrontal cortex and the anterior cingulate cortex (brain structures related to control of emotions including fear). To summarize, the brain imaging research provides a possible biological explanation for the key symptoms in PTSD, including memory problems, increased fear response, and a decreased ability to inhibit this response.

Despite significant group differences, it is important to note that the size of the hippocampus (and other regions of interest) of an individual with PTSD could be similar or even identical to the size of the hippocampus of an individual without PTSD. Since there is a significant overlap in brain structure and function between individuals with and without PTSD, neuroimaging techniques cannot be used currently to diagnose this disorder. (See Appendix E for bibliography).

II: Potential Benefits of Research Using Neuroimaging Techniques for Wounded, Ill, and Injured Service Members with PTSD

Neuroimaging techniques have contributed to the recognition of structural and functional brain abnormalities in PTSD, and helped us understand how this disorder develops after trauma exposure. Structural and functional changes confirmed by neuroimaging techniques can potentially be used to target these abnormal brain regions for treatment. Neuroimaging may also help predict individuals who are at risk of developing PTSD, and could help with the development of new treatments that prevent PTSD. Since evidence indicates that there are likely many types of PTSD, reliable identification of the different PTSD types through use of neuroimaging techniques could improve the ability to predict the progression of this disorder, and determine the response to varied treatments. Neuroimaging research is currently underway to identify predictors of response to PTSD treatment. Unique brain patterns associated with successful and unsuccessful PTSD treatment could help clinicians and patients make informed choices about individualized treatment with medications or psychotherapy (talk therapy). Neuroimaging techniques may also help differentiate PTSD from other disorders that present with similar symptoms, such as mild Traumatic Brain Injury (mTBI) and depression. An accurate method to distinguish and accurately diagnose disorders with overlapping symptoms is critical, as these conditions have different disease progressions, and therefore require different types of treatment and rehabilitation.

III: Collaborative Interagency and Extramural Research on the Use of Neuroimaging in PTSD Diagnosis

The DoD currently collaborates with researchers from the VA, academia, and Draper Laboratory to investigate PTSD using neuroimaging techniques. Detailed tables that list the principal investigator, institutional affiliation, institutional collaboration, proposal title, types of imaging techniques, and imaging targets can be found in Appendices B, C, and D. The DoD currently funds 23 ongoing neuroimaging studies on PTSD and TBI. Four studies focus on differentiating PTSD from mTBI, six studies focus on identifying those at risk for developing PTSD, six studies evaluate predictors of response to treatment, and seven studies evaluate brain changes in PTSD (Appendix B). The VA and the NIMH funded 8 and 14 PTSD neuroimaging studies, respectively (Appendices C and D). The DoD collaborates with the VA and the NIMH to regularly review the research portfolios of their respective agencies. This coordinated review ensures oversight of currently funded DoD, VA, and NIMH research studies, and prevents duplication of funding allocation for similar projects.

CONCLUSIONS

- Current research does not support the use of neuroimaging to identify or diagnose PTSD in an individual patient.
- The use of neuroimaging in PTSD should currently be considered in the realm of research, and not for use in the diagnosis or care of an individual patient in the clinic.
- Neuroimaging research findings have confirmed that PTSD is associated with structural and functional abnormalities in the brain regions related to memory and fear response, and have helped facilitate an understanding of the biology and development of PTSD.
- Future neuroimaging research has the potential to identify those at risk for PTSD, determine different types of PTSD, and develop new tools that can help match patients with optimal treatments.
- Neuroimaging research has the potential to help accurately diagnose PTSD by distinguishing it from other conditions with overlapping symptoms, such as mTBI.
- The DoD is currently collaborating with the VA, academia, and Draper Laboratory by funding 23 research studies in PTSD and related conditions to investigate the utility of neuroimaging in the diagnosis, biology, and treatment of PTSD.
